

AIR TREATMENT APPARATUS AND METHODS

Background

This invention relates to a new air treatment apparatus and methods for
5 treatment of air.

Air treatment, i.e., the process of treating air to remove undesirable materials, is of great interest as advances in research continue to suggest that breathing purer air has tangible health benefits.

One known type of air treatment, referred to as air ionization or electron
10 generation, involves using a source of electricity to produce a charge and generate negative ions. Contaminants suspended in air, such as dust, smoke and pollen, are usually made up of small positively-charged particles. The earth, buildings and other large objects are also positively charged, and thus tend to repel these particles, which keeps them in suspension. Negative ions are beneficial because they combine with the
15 positive particles and neutralize them, and the resulting combinations fall to the earth or floor under the action of gravity because they are heavier than air. As a result, the "ionized" air has fewer suspended particles.

Most conventional air ionizers use corona discharge to produce a charge on a surface to generate negative ions. Corona discharge devices involve high voltages and
20 may have a high capacitance, so the user's inadvertent contact with a charged collector surface may lead to an undesirable shock.

Another known type of air treatment called photo-ionization involves producing ozone by subjecting the oxygen in air to ultraviolet light at a known wavelength (about 185 nm). Ozone is an effective oxidizer of organic substances, including bacteria,
25 algae, mildew and mold, and helps to eliminate odor.

It would be desirable to provide an apparatus that would allow for treatment of air by negative ionization and photo-ionization in a single unit. It would also be desirable to provide for treatment of volatile organic compounds (VOCs), which are not generally susceptible to ozone oxidation.

Description of Drawings

Figs. 1 and 2 are front and rear perspective views, respectively, of one implementation of a new air treatment unit.

Fig. 3 is a sectional view in elevation of the air treatment unit of Fig. 1, viewed 5 along a line at arrows 3-3 in Fig. 1.

Fig. 4 is an exploded front perspective view of a housing of the air treatment unit of Fig. 1.

Fig. 5 is an exploded assembly view of components within the housing of the air treatment unit of Fig. 1.

10 Fig. 6 is a view of a lower end of an inner tray shown in Fig. 5 assembled with a bulb.

Fig. 7A is a top view of a modified tray, Fig. 7B is a slightly enlarged end view showing a bulb within the modified tray, and Fig. 7C is a slightly enlarged side view of the modified tray.

15

Detailed Description

In a new air treatment unit, ambient air, such as air within a living space, is treated to make it more healthy to breathe.

According to one aspect of the new air treatment unit, a negative ion generation 20 unit that creates negative ions is provided together with a photo-ionizer. The negative ion generator has an exposed outer surface that is a high dielectric, i.e., substantially nonconductive, and an enclosed inner conductive surface that becomes charged. Negative ions generated at the outer surface are transferred to air via a negative electrostatic field.

In specific implementations, a power supply that supplies power to the negative 25 electron generator overcomes the bound charges and is self-limiting.

The photo-ionizer or photo-ionizing assembly has a light source that emits ultraviolet light. When oxygen in air is subjected to the ultraviolet light, the oxygen forms ozone.

According to another aspect, some of the ultraviolet light produced by light source is caused to strike a target material. The target material includes a catalyst that causes peroxide radicals and super-oxide ions to be produced. The peroxide radicals and super-oxide ions react with VOCs in air and reduce them. Also, because this portion of the ultraviolet light is used to form peroxide radicals and super-oxide ions, and not to produce ozone, the overall production of ozone, which can be an irritant in high quantities, is regulated.

5 General

As shown for one implementation in Fig. 1, an air treatment unit 10 has a base 10. 12 and a generally frustoconical housing 14 extending upwards from the base 12. The housing 14 tapers in diameter from its lower end 15a adjacent the base 12 to an upper end 15b at the top surface 16. The top surface 16 slopes upwardly from a front side 17a, which is shown in Fig. 1, to a rear side 17b, which is shown in Fig. 2.

Referring to the cross-section of the air treatment unit 10 shown in Fig. 3, the 15 assembled base 12 and housing 14 define a generally enclosed interior 18. Air enters the interior, circulates therein and eventually exits as shown by the arrows. The rear side 17b has louver openings formed therein that are arranged in an upper air inlet portion 20 and a lower air outlet portion 22. Openings 24 (Figs. 1 and 2) between the base 12 and the lower end 15a of the housing 14, as well as a gap 26 (Figs. 1 and 3) in 20 the top surface 16, also serve as additional air outlet openings.

A fan 28 is positioned within the interior 18 adjacent the air inlet portion 20 to draw air into and generate an air flow through the housing 14. Air within the housing flows upwardly and around a photo-ionization assembly 34. Ultraviolet light from the photo-ionization assembly 34 causes oxygen in the air to form ozone.

25 In operation, which is described below in greater detail, a substantial portion of any given volume of air flowing through the housing 14 is treated by (1) neutralizing positively charged particles through their interaction with the negative ions (which also occurs in surrounding air outside the housing) and (2) oxidation (through the production of ozone by photo-ionization). Optionally, photo-ionization may also include the

production of certain radicals and ions (through ultraviolet light striking a target) that reduce VOCs, as is also described below.

Construction

Figure 5 is an exploded assembly view showing the base 12 and the components 5 within the housing 14.

The negative ion generator 32 is a hollow, generally cylindrical structure that tapers slightly from its open lower end to its closed upper end. The lower end is received within the base 12. An upper surface of the base 12 and an inner surface 59 of the negative ion generator 32 together define a chamber therein. The negative ion 10 generator 32 is formed of a high dielectric material, such as melamine, and the outer surface 30 is therefore substantially non-conductive. The inner surface 59 is made to be conductive, e.g., as through application of a coating of graphite.

A mounting member 36 has a mounting plate 38 positioned above the negative ion generator 32 (Fig. 3) and spaced apart legs 40 that are attached to the base 12 with fasteners. In the assembled unit 10, the legs 40 are positioned adjacent but slightly spaced from the outer surface 30 of the negative ion generator 32 as shown in Fig. 3 to allow air circulation.

A support member 42 is attached at a rear side of the mounting plate 38, e.g., with fasteners. The fan 28 is coupled to an upright portion 44 of the support member 42 20 with fasteners. An angled portion 46, which is cantilevered from the upright portion 44, provides a support for the photo-ionization assembly 34.

The photo-ionizing assembly 34 includes a tray (having an outer tray 48, an inner tray 50 nested within the outer tray 48 and a tray end 52) and a fluorescent bulb 90. Apertures 53a, 53b and 53c in the inner tray 50, outer tray 48 and angled portion 25 46, respectively, provide for increased air flow into and around the ionization assembly 34. An electrical connection, e.g., a socket (not shown), for the bulb 90 is provided on the angled portion 46 adjacent a lower end of the tray.

The fluorescent bulb 90, which produces ultraviolet light, typically has two ceramic ends 91a, 91b and a substantially cylindrical transparent lighting surface 92

between the two ends 91a, 91b. The end 91a has electrical terminals for establishing an electrical connection.

When assembled, the ends 91a, 91b of the bulb 90 are received within openings 93a, 93b in the inner tray 50, respectively, with the end 91a also extending through an opening 94a in the outer tray 48. When assembled, the lighting surface 92 of the bulb 90 is spaced from the inner tray 50.

Optional, an inner surface 51 of the inner tray 50 may be provided with a target material. In a specific implementation, the target material is provided as a coating on the inner surface 51, and the coating is applied to substantially all of the inner surface 51. If the inner tray includes an optional coil 95 as shown in Figs. 7A, 7B and 7C or a similar mesh or screen-like structure, the coil 95 or the structure may also be provided with the target material.

Figs. 7A, 7B and 7C show an implementation of the inner tray 50 is with the optional coil 95 extending between the openings 93a, 93b. The coil 95 is configured of a series of spaced rings each having an opening sized to receive the installed bulb 90, yet remain spaced from the lighting surface 92. Fig. 7B shows the end 91a received within the opening 93a and the coil 95 radially spaced from the lighting surface 92. Further details regarding the coating are described below.

Referring to Fig. 4, a generally elliptical opening 54 is defined in the upper surface 16 of the housing 14. A lens 56, which is formed of a translucent polycarbonate material, is fitted with a slightly smaller opaque lens center 58 and received within the opening 54. The lens 56 has apertures 60 extending through to the interior 18 of the housing 14. Air can exit the interior 18, pass through the apertures 60, and exit the housing 14 via the gap 26 between the lens 56 and the lens center 58. As an added feature, if the lens 56 is formed of a translucent or transparent material, the lens 56 may be lit by the bulb 90 during operation of the unit 10 and appear as an elliptical ring.

An opening 62 sized for the tray end 52 is defined in the housing 14 above the air inlet portion 20. The opening 62 allows the photo-ionization assembly to be slidably removed from or inserted into the unit 10 (e.g., to inspect and/or replace the bulb 90)

without disassembling the housing 14 and the base 12, which requires more time and effort, and may expose other components to potential damage.

Electrical Circuit

The air treatment unit 10 is designed to operate on normal household 110 V
5 power supplied through a power cord 80. A power switch 82 allowing the unit to be turned "ON" or "OFF" is positioned in a recess 84 on the rear side 17b of the housing 14.

Power is fed to the power supply 86, which is shown in Fig. 5. The air treatment
unit 10 operates at a substantially constant voltage. The power supply 86 provides
10 power to the fan 28, the negative ion generator 32 and a ballast 88 via conventional
wiring, which has been omitted for clarity.

The electrical connection from the power supply 86 to the negative ion generator 32 is a single lead from the negative side of the power supply extending through the outer surface 30 to the inner surface 59, which supplies about 20,000 volts at 20 kHz to
15 create the negative charge on the conductive inner surface 59 and eliminate the bound charges on the surrounding dielectrics. The supplied power is sufficient to provide a negative charge equivalent of at least 10,000 volts.

The electrical connection between the power supply 86 and negative ion generator 32 is also self-limiting in that as the electrostatic field adjacent the negative
20 ion generator 32 decreases from a positive value to zero, less power will be supplied so that fewer electrons will be generated. Thus, the self-limiting aspect of the power supply 86 prevents a high negatively charged environment from developing, which would tend to keep particles suspended, rather than allowing them to settle as desired.

In one specific implementation, the power supply 86 includes a feedback loop
25 with a limiting output resistor such that the voltage supplied to the negative ion generator decreases as the electrostatic field decreases from a positive value to zero.

The ballast 88, which is connected to the fluorescent bulb 90, limits the current supplied to the bulb 90 and provides an inductive "kick" to initiate ionization of the bulb 90.

In a specific implementation, suitable electrical components are as follows:

- Power supply 86: Collmer Semiconductor Series 2073 with custom features
- Fan 28: Pelonis Model No. PM8025-7 AC Series Fan (80 mm sq. x 25 mm)
- Ballast 88: Robertson Transformer (now Robertson Worldwide) Catalog
5 No. SSGPH287 P magnetic ballast
- Bulb 90: Light Sources Inc. No. GPH118T5VH/4 single-ended 4-pin
germicidal bulb.

Operation

In photo-ionization, ultraviolet light at a wavelength of 185 nm striking oxygen
10 in air will create ozone. The flow rate of the air past the bulb 90, as well as the wavelength and intensity of the light, can be varied to produce ozone at a desired rate. In some implementations, a germicidal light source is used, in which case the bulb 90 emits ultraviolet light at a wavelength effective to kill microorganisms (254 nm), as well as at 185 nm.

15 Although ozone is an effective oxidizer, other approaches to reducing airborne VOCs produce even better results. In photocatalytic oxidation, VOCs that have been adsorbed from air onto a catalyst surface in the air flow are oxidized by peroxide radicals and super-oxide ions. These peroxide radicals and super-oxide ions may be created by causing ultraviolet light to strike a target material. Photocatalytic oxidation
20 is desirable because VOCs are significantly reduced, rather than being simply captured (e.g., by filtering), which requires their subsequent removal.

Photocatalytic oxidation may be combined with ozonation such that light from the same light source produces ozone as well as the peroxide radicals and super-oxide ions. Photocatalytic methods and apparatus are disclosed in U.S. Patent Application
25 No. _____, which was filed on July 12, 2000 under the title "Air Treatment Apparatus" and names Ronald G. Fink as the inventor, and which is incorporated herein by reference.

In the air treatment unit 10, the inner surface 51 of the inner tray 52 can be coated or painted with a target material containing at least 10% titanium dioxide by

weight. In specific implementations, the target material may also be formulated as 10-30% titanium dioxide, 0-30% silver and 0-30% copper, by weight. Periodic reapplication of the coating may be required.

As can be seen from Fig. 5 and 6, the inner surface 51 is shaped and positioned 5 such that it is directly opposite the lighting surface 92 of the bulb 90 over substantially its entire length and over more than half of its circumference. Specifically, the inner surface 51 is positioned such that it is opposite a first circumferential portion 97a of approximately 210°, with an adjoining second portion 97b being defined as the remaining approximately 150°. Ultraviolet light emitted in straight rays (i.e., radially) 10 from the first portion 97a is directed toward the inner surface 51, and the portion thereof that reaches the inner surface 51 causes the target material to produce peroxide radicals and super-oxide ions. Ultraviolet light emitted through the second portion 97b normally does not impinge upon the inner surface 51 (and thus does not impinge upon the target material), and therefore this portion of light may generate ozone but not the peroxide 15 radicals and super-oxide ions.

It can be seen that varying the proportion of ultraviolet light that strikes the target material relative to the portion that does not strike the target material allows regulation of the production of ozone. For example, referring to the implementation of the inner tray 50 with the coil 95 as shown in Figs. 7A, 7B and 7C, the target material 20 can be provided on the surface of the coil 95, in which case the target material is closer to the ultraviolet light source (i.e., the bulb 90), more target material is impinged upon by the ultraviolet light, and, correspondingly, more peroxide radicals and super-oxide ions are produced. Ultraviolet light passing through the spaces between rings of the coil 95 and not striking the target material still produces ozone.

25 It should be noted that with a coated coil in place, there is no non-impingement portion 97b that can be defined, because at least some light rays from all angles will strike portions of the coil 95.

Although the coil 95 as shown in Figs. 7A, 7B and 7C has is comprised of about 10 turns or rings that would encircle the bulb 90, the spacing between the rings can be

reduced to produce more peroxide radicals and super-oxide ions. Correspondingly, increased spacing, i.e., fewer rings, would produce fewer peroxide radicals and super-oxide ions.

As would be appreciated by those of skill in the art, structures similar to the coil
5 configuration, such as a mesh, a screen or a perforated tube may be used, with the construction and sizing being determined according to the desired relative amounts of ozone and peroxide radicals/super-oxide ions, based upon the relative area through which ultraviolet light passes unimpeded (for producing ozone) and the area coated with target material (for producing peroxide radicals and super-oxide ions).

10

Materials

Except as specifically noted, the various components may be made of any suitable material. In a specific implementation, the housing 14, support member 42, outer tray 48, inner tray 50 and tray end 54 are all made of a plastic, e.g., polycarbonate or UV stabilized ABS.

15

It is to be understood that the present invention includes all such modifications as may come within the scope and spirit of the following claims and equivalents thereof.
